(Accepted 31 October 1996)

This work continues the analysis of variable density flow in groundwater systems. It focuses on both thermohaline (double-diffusive) and three-dimensional (3D) buoyancy-driven convection processes. The finite-element method is utilized to tackle these complex, non-linear problems in two and three dimensions. The preferred numerical approaches are discussed regarding appropriate basic formulations, balance-consistent discretization techniques for derivative quantities, extension of the Boussinesq approximation, proper constraint conditions, time marching schemes, and computational strategies for solving large systems. Applications are presented for the thermohaline Elder and salt dome problem as well as for the 3D extension of the Elder problem with and without thermohaline effects and a 3D Bécard convection process. The simulations are performed by using the package FEFLOW. Conclusions are drawn with respect to numerical efforts and the appropriateness for practical needs. © 1998 Elsevier Science Limited. **2 INTRODUCTION**

Thermohaline (or double-diffusive) convection processes are connected with the presence of heterogeneous temperature and concentration fields. Thus, convective currents can arise from heat and salinity gradients acting simultaneously (e.g. Refs 2, 8, 52–54, 59, 60, 67, 72, 73). Geophysical applications of thermohaline models can be found for instance in the field of geothermics and waste disposal in salt formations.\(^8\) Thermohaline effects are important for the production of mineralized thermal water, the re-injection of cooled brine into heated deep aquifers connected with geothermal supply technologies, and groundwater movement near salt domes.

Usually, the phenomena of double-diffusive convection (DDC) are related to the presence of both: (1) at least, two properties (substances, thermal energy) stratifying the fluid and having different diffusivities; and (2) opposing effects on the vertical density gradient.\(^8\) Accordingly, different regimes can be distinguished: a 'diffusive regime' occurs if the destabilizing potential comes from the property with the larger diffusivity, e.g. a stable salinity gradient is heated from below. On the other hand, a 'finger regime' exists if the driving (destabilizing) forces are caused by the more slowly diffusing property, e.g. hot saline fluid on top of a stable temperature gradient. Both regimes can also
appear in a differentiated form referred here to as a 'mixed DDC regime' if both properties can destabilize and affect the fluid during the temporal development, e.g. a heavy cool solute sinks down to a region which is heated from below, so a finger regime at the beginning converges more to a diffusive regime over time.

The first part of the paper by Kolditz et al.\textsuperscript{43} mainly focused on the verification of numerical schemes against available benchmarks for density-coupled convection processes. Established test examples (e.g. the Henry problem, Elder problem, and salt dome problem) are only 2D and single-diffusive (either mass or heat-driven) convection processes. But even for these academic, seemingly simplistic 2D problems a number of discrepancies appear, still, for most recent findings.\textsuperscript{55} It has been shown\textsuperscript{43} that numerical schemes with their spatial and temporal resolutions can essentially influence computational results. Figure 1 recalls the contradictory results for the Elder problem as well as the salt dome test case obtained by different authors. While Elder\textsuperscript{23} and the recomputation done by Voss and Souza\textsuperscript{55} used obviously overdiffusive schemes on relatively coarse grids, newer findings\textsuperscript{53,55} with refined spatial and temporal discretizations reveal convection patterns that are distinctly different from former work. The flow field now indicates a central upwelling rather than downwelling. More dramatically, Oldenburg and Pruess\textsuperscript{55} recently presented new results for the salt dome problem (HYDROCOIN level 1 case 5). They believe they achieved much more accurate solutions for this example. However, their results are fully outside of all results known to date (Fig. 1(b)). In fact, their 'swept forward-type' solutions are suspiciously very near to the pure freshwater case without any density coupling, so TOUGH2's results become widely questionable for problems involving velocity-dependent dispersion effects.

A possible reason for this discrepancy is recently indicated by the work of Konikow et al.\textsuperscript{44} They showed that a salinity pattern of a swept forward type appears if constrained boundary conditions for the salt dome interface are applied (allowing only dispersive release of brine and precluding any convective release of brine). While the study by Konikow et al.\textsuperscript{44} is more physically motivated it also gives an indication of the importance of a mathematically (numerically) correct handling of boundary conditions for this type of problem, independently of the physical appropriateness or not.

In the past, Galerkin methods, finite differences (FDM) and finite element methods (FEM) have been employed to solve the non-linear coupled balance equations for variable density groundwater problems in 2D. Pinder and Cooper\textsuperscript{57} used the method of characteristics. Finite elements based on a primitive \(u-v-p\)-variable formulation are utilized by Segol et al.,\textsuperscript{56} Huyakorn and Taylor\textsuperscript{38} and Diersch.\textsuperscript{13-15} However, the subsequent works desisted from primitive variable approaches because their increased accuracy was shown to be in disproportion to the increased numerical effort and inherent restrictions in formulating boundary conditions. Accordingly, standard formulations succeeded that are based on substituting the Darcy law in the primary balance equations. Recent works devoted to this

(a) Simulated concentration pattern at 20 years for the Elder problem with a Rayleigh number of 400; (left) results obtained by the SUTRA simulator (Voss and Souza\textsuperscript{55}), (solid curves) and by Elder\textsuperscript{23} (dashed curves), and (right) computed by the FEFLOW simulator in agreement with the results attained by ROCKFLOW and TOUGH2 as discussed by Kolditz et al.,\textsuperscript{32} and (b) salt dome test case: (left) TOUGH2 results\textsuperscript{55} against (right) FELOW (and ROCKFLOW) findings\textsuperscript{45} for steady-state with mechanical dispersion of \(\beta_L = 20\) m and \(\beta_T = 2\) m.}
\end{figure}
subject are presented, among others, by Frind,26 Diersch et al.,95 Voss and Souza,46 Diersch,47 Hassanizadeh and Leijnse,61 Herbert et al.,32 Galeati et al.,27 Schincariol et al.,63 Fan and Kahawita,25 Oldenburg and Pruess,55 Croucher and O’ Sullivan,12 Zhang and Schwartz,79 and Kolditz.42 On the other hand, the third-dimensional applications are related to field problems as given by Huyakorn et al.,39 Kakinuma et al.40 and Xue et al.76 and do not consider rigorously the density coupling mechanisms. However, there are some theoretical and numerical works in three-dimensional free convection problems mostly focused on the (cavity) Horton–Rogers–Lapwood (HRL) problem34 presented by Holst and Aziz,44 Zebib and Kasso,79 Straus and Schubert,86,87 Horne,86 Schubert and Straus,84 Caltagirone et al.9 Chan and Banerjee,10 and Beukema and Bruin.6

It is obvious from the above that the extension to thermohaline and/or 3D density-coupled convection problems will significantly increase the importance of both getting a physically equivalent process description in the discretized models and overcoming the numerical burden, particularly if aiming at practical problems. In the following, relevant numerical aspects are discussed in the context of the FEM. The developed solution strategies are implemented in the 3D finite-element simulator FEFLOW.20 FEFLOW is employed to study 2D and 3D, thermohaline and buoyancy-driven convection problems from various perspectives. First, we expand the 2D Elder and salt dome problems to thermohaline processes in order to study thermal influences on groundwater-brine flow systems. Second, we extend the original Elder problem to 3D for both single-diffusive (solutal) and double-diffusive (thermohaline) convection processes to analyze the evolution of 3D pattern formations in comparison with the 2D counterparts. Finally, we consider a Bénard problem as an example of more complex 3D multicellular convection in a porous layer. The presented results for thermohaline and solutal convection systems may provide examples for a comparison analysis in 2D and 3D by using alternative approaches.

3 BASIC EQUATIONS

The governing equations for the coupled mass and heat transport in groundwater (saturated porous medium) are derived from the basic conversion principles for mass, linear momentum, and energy.43 The following non-linear system finally results,28,22 which has to be solved in two and three dimensions

\[
S_0 \frac{\partial h}{\partial t} + \frac{\partial q_f}{\partial x_i} = Q_p + Q_{eb}(C, T)
\]  

\[
q_f = -K_q f_p \left( \frac{\partial h}{\partial x_j} + \frac{\partial \rho_f}{\partial \rho_p} \epsilon_f \right)
\]

As seen, a hydraulic-head-conductivity-(h-K)-form of the Darcy equation (2), instead of the pressure-permeability-(p-k)-form, is preferred in FEFLOW, which usually permits more convenient formulations of boundary conditions and parameter relations for applications in subsurface hydrology. As a result, the tensor of hydraulic conductivity \( K_q \) refers to the reference density \( \rho_p \) and the reference viscosity \( \mu_p \), which are, on the other hand, related to the proper reference conditions for the concentration \( C_0 \) and the temperature \( T_0 \). For such a formulation a viscosity relation function \( f_p \), in eqn (5), appears to include viscosity effects in Darcy’s law (2). The following

\[
\frac{\partial}{\partial t} (RC) + \frac{\partial}{\partial x_i} \left( q_f C - D_q \frac{\partial C}{\partial x_j} \right) + R \theta C = Q_C \text{ divergent form}
\]

\[
R_d \frac{\partial C}{\partial t} + q_f \frac{\partial C}{\partial x_i} - \frac{\partial}{\partial x_i} \left( D_q \frac{\partial C}{\partial x_j} \right) + (R \theta + Q_p) C = Q_C \text{ convective form}
\]

\[
\left[ \epsilon \rho_f \rho^* + (1 - \epsilon) \rho^* \right] \frac{\partial T}{\partial t} + \rho^* \frac{\partial T}{\partial x_i} \left( \frac{\partial T}{\partial x_j} \right) = Q_T
\]

To close the set of balance equations the following constitutive formulations are additionally needed:

\[
\rho^* = \rho_p \left[ 1 + \frac{\alpha}{(C - C_0)} (C - C_0) - \beta(T - T_0) \right]
\]

\[
h = \frac{\rho_f}{\rho_0} + x_l \quad K_{ij} = \frac{k_{ij} \rho_f g}{\mu_0}
\]

\[
\alpha = \left[ \frac{\rho^*(C) - \rho_0^*}{\rho_0^*} \right] / \rho_0 \quad f_p = -\frac{\mu_f^*}{\rho_f^* (C, T)}
\]

\[
D_q = \left( \epsilon D_q + \beta_T V_q \right) \delta_{ij} + (\beta_L - \beta_T) \frac{q_f q_j}{V_q^2}
\]

\[
R = \epsilon + (1 - \epsilon) \chi(C) \quad R_d = \epsilon + (1 - \epsilon) \frac{\partial [\chi(C) \cdot C]}{\partial C}
\]

\[
\lambda_{ij} = \lambda_{ij}^{cond} + \lambda_{ij}^{disp} \quad Q_T = \epsilon \rho^* \left[ \frac{\partial T}{\partial x_j} + (1 - \epsilon) \rho^* \right]
\]

\[
\lambda_{ij}^{cond} = \left[ \epsilon \lambda^* + (1 - \epsilon) \lambda^* \right] \delta_{ij}
\]

\[
\lambda_{ij}^{disp} = \rho^* \rho^* \left[ \alpha_T V_q^2 \delta_{ij} + (\alpha_L - \alpha_T) \frac{q_f q_j}{V_q^2} \right]
\]
constitutive polynomial expression is used

\[
f_\mu = \frac{\mu^{\mu}}{\mu^{\mu}(C, T)} = \frac{1 + 1.85\omega(C=C_s) - 4.1\omega(C=C_s) + 44.5\omega^2(C=C_s)}{1 + 1.85\omega - 4.1\omega^2 + 44.5\omega^3} \frac{1 + 0.7063\sigma - 0.04832\sigma^3}{1 + 0.7063\sigma(T=T_r) - 0.04832\sigma^3} \tag{6}
\]

which is a combination of empirical relationships given by Lever and Jackson\cite{49} for high-concentration saltwater and by Mercer and Finder\cite{50} for geothermal processes in the range between 0 and 300°C. In practice, the expansion coefficients \( \hat{\alpha} \) and \( \hat{\beta} \) of eqn (5) are, in most cases, considered as constant.\cite{51} For the present investigations we shall also use this assumption to maintain an unified parameter basis for comparison purposes. However, it should be mentioned in a geothermal context where large temperature variations occur and buoyancy forces are dominant, that this approach is often not appropriate.\cite{52} Based on the theoretical framework done by Perrochet\cite{53} FEFLOW is also capable of handling a non-linear variable thermal expansion \( \hat{\beta}(T) \) in the form of a fifth-order polynomial to match the fluid density variation over a wide temperature range with a high accuracy and to satisfy the zero condition (density anomaly) at 4°C. For more details see Diersch.\cite{22}

The divergent form and the convective form of the contaminant mass transport equation (3) (the energy balance equation (4) has already led to a convective form after introducing the temperature) are physically equivalent. Commonly, the convective form of the transport equation is preferred for numerical approximations because simpler boundary-value problems are accessible.

It is known\cite{28} the Boussinesq approximation becomes insufficient for large density variations (e.g. at high-concentration brines or high-temperature gradients). The main difference between the Boussinesq approximation and the actual balance quantities is expressed by the additional term \( Q_{EB}(C, T) \) in the continuity equation (1) according to

\[
Q_{EB}(C, T) = -c\left(\frac{\hat{\alpha}}{(C_t - C_s)} \frac{\partial C}{\partial t} - \hat{\beta} \frac{\partial T}{\partial t}\right)
- q_l\left(\frac{\hat{\alpha}}{(C_t - C_s)} \frac{\partial C}{\partial x_l} - \hat{\beta} \frac{\partial T}{\partial x_l}\right) \tag{7}
\]

which is neglected if the Boussinesq approximation is assumed. The first term in eqn (7) can be omitted if the temporal changes in concentration and/or temperature vanish. However, even the evolving features of a convection process may be thoroughly affected at higher density contrasts (problems of bifurcation, physical instability and hydrodynamic pattern formation). The second term of eqn (7) can be ignored if the density gradient is essentially orthogonal to the velocity vector. This is quite often not a tolerable assumption. Note, eqn (7) has to be modified in the case of a non-linear variable thermal expansion \( \hat{\beta}(T) \).\cite{22}

4 SPATIAL DISCRETIZATION

The above eqns (1) to (4) are discretized by the FEM using bilinear or biquadratic elements for 2D, and prismatic pentahedral trilinear or hexahedral trilinear and triquadratic elements for 3D. Finally, it yields the following coupled matrix system

\[
\begin{align*}
O\dot{h} + S(h, C, T)h & = F(h, q, C, \dot{C}, T, \dot{T}) \\
Aq & = B(h, C, T) \\
P(C)\dot{C} + D(q, C)C & = R(C) \\
U\dot{T} + L(q, T)T & = W(T)
\end{align*}
\tag{8}
\]

where \( h \), \( q \), \( C \) and \( T \) represent the resulting vectors of the nodal hydraulic head, Darcy fluxes, contaminant concentration and temperature, respectively. The dot means differentiation with respect to time \( t \). The matrices \( S, A, O, P \) and \( U \) are symmetric and sparse, while \( D \) and \( L \) are unsymmetric and sparse. The remaining vectors \( F, B, R \) and \( W \) encompass the right-hand sides (RHS) of eqns (1) to (4), respectively. The main functional dependence is shown in parenthesis.

The individual finite-element formulations of the matrix system (8) as realized in FEFLOW are summarized in Appendix A. Note, different formulations result for the divergent and the convective forms of the transport equations. Although physically equivalent, they can deliver different numerical solutions due to their different boundary-value formulations.

Another point of view is related to the numerical evaluation of the Darcy fluxes \( q \) for a given discretization. The success of a numerical solution for variable density flow problems is essentially dependent on an appropriate choice of suitable schemes for computing derivative quantities from the Darcy equation.

5 CONTINUOUS APPROXIMATION OF VELOCITY FIELDS

The substitution of Darcy fluxes (2) in the continuity eqn (1) gives immediately an equation to determine the unknown hydraulic head \( h \) according to the weak
formulation (A3) in Appendix A. If $h$ is known and assuming initial $C$ and $T$ distributions, the fluxes $q$ can be directly computed via Darcy’s equation (2). However, a careful handling of derivative quantities is required. As normally done in FEM, piecewise continuous ($C^0$) basis functions $N_m$ (Appendix A) for the hydraulic head $h$ generate velocity fields $q$ (using derivatives of hydraulic head) that exhibit discontinuities across element boundaries. It results in non-unique values at nodal points. Particularly for buoyancy-influenced flows, discontinuous (non-unique) velocities can cause difficulties (spurious vertical velocities) in the numerical solution due to inappropriate balance approximation of the lower order term $\partial h / \partial x_j$, behaving constantly in an element for the case of linear basis functions, and the higher order gravitational term $[\rho'(C, T) - \rho_0]/\rho_0$, varying linearly in an element for linear basis functions, of the RHS of the Darcy eqn (2). This has already been addressed in previous works and different numerical schemes were proposed to overcome these problems.

Voss and Souza preferred, for the SUTRA code in 2D, a reduced-order approximation of the buoyancy term; actually the concentration is averaged in every element, therefore, the pressure gradient and the concentration distribution have the same spatial variability, practically constant (for linear basis functions). This is called a consistent velocity evaluation. Leijnse showed that such a consistent velocity approximation can be interpreted as an average of the local gravity component in the local directions of a finite element. A generalization of this spatial averaging has recently been presented by Knabner and Frolkovic. Instead of reducing the approximations Herbert et al. introduced a mixed interpolation strategy in NAMMU for 2D, where the pressure is approximated by quadratic elements to obtain a linearly distributed pressure gradient which becomes consistent with a linear distribution of the concentration-dependent buoyancy term. Clearly, quadratic basis functions increase the computational expense and, especially for 3D, an alternative approach is preferable.

Taking into consideration that the discretized balance terms of the conservation equations generally provide a different spatial variability (compare the ‘diffusion’ term against the ‘convective’ term or a ‘reactive’ term), a consistent approximation by the FEM means that all terms have to be rigorously weighted at nodal points. As a result, unique values of even discontinuous variables are generated at nodal points. This principle is consequently also applied to the velocity evaluation and leads to approaches referred to as smoothing techniques used in FEFLOW for the present analysis. Lee et al. thoroughly discussed both global and local smoothing techniques for derivative quantities. In this light, the weak form of the Darcy equation (A4) in Appendix A can be recognized as a global smoothing procedure which was introduced in the water resources literature by Yel. Today, smoothing techniques have an additional meaning for adaptive methods to compute higher order solutions for an error estimation. Appendix B summarizes the smoothing techniques available in FEFLOW and which are appropriate for the present simulations of coupled phenomena. While global derivative smoothing schemes with a consistent mass matrix require a higher numerical effort, lumped mass smoothing algorithms as well as simpler local smoothing schemes are the most cost-effective approaches and have been shown to be well-suited for the present class of problems. The latter is to be recommended for large 3D problems.

Smoothed velocities of a higher-order approximation lead to a continuous distribution of all velocity components in a mesh. As a consequence, continuous fields also exist along material interfaces, e.g. between media with different hydraulic conductivities, where an interface nodal point shares these different media and, naturally, a weighted average of the flux quantities results. Leijnse pointed out that physically unrealistic results can be obtained for cases where the conductivity in adjacent elements differs by more than two orders of magnitude. Indeed, if utilizing such continuous velocity fields from a mesh having an insufficiently adapted interface, discretization particle tracking procedures can lead to poor results if starting pathlines near such an interface location (a particle may effectively be propagated into media with low hydraulic conductivity). On the other hand, a discontinuous velocity field approximation often gives significant problems when a particle crosses an element. Then, a particle can be ‘caught’ in the interface due to components that have opposite directions across an element edge, as indicated by Sauter and Beusen, who introduced special transition elements with interpolated (smoothed) velocity properties to overcome these difficulties. As the sum, the higher-order approximation of continuous velocities is the most natural approach in the finite element method and needs no ad hoc techniques in adapting interface conditions, provided, however, the interface is appropriately discretized. The necessity for a continuous flow field approximation, also in the context of modelling heterogeneous media, is thoroughly discussed in the work covering mixed hybrid finite element techniques presented by Mosè et al. followed by recent discussions given by Cordes and Kinzelbach and Ackerer et al.

6 CONSTRAINTS AND RELATED BUDGET ANALYSIS

Constraints of boundary conditions can play an important role in practical modelling of variable density transport. Typically, in saltwater encroachment problems, the boundary conditions of freshwater and
saltwater are dependent on the in/outflowing characteristics essential to a correct mathematical formulation. However, most prior works\textsuperscript{27,32,38,44,55,66,75} did not consider such conditions in a rigorous manner. To identify the problem let us consider, for instance, the salt dome flow problem as schematically shown in Fig. 2.

Alternating boundary concentrations appear on the top boundary depending on the dynamic process. As long as water enters the domain it should have a prescribed concentration of freshwater. However, if the water leaves the domain (along the same upper boundary) the concentration on this boundary is unknown and should be computed. Such a description can be easily realized if the entire boundary section is assigned by a freshwater boundary condition of the first kind \((C = C_R^F)\) and, at the same time, the boundary will be imposed by a constraint condition in the form of a null minimum mass flux \(Q_C^{min} = 0\). Such an arrangement guarantees that the freshwater condition remains valid as long as the convective mass flux, being concentration-dependent due to the density variation, points into the domain.

A rigorous handling of such constraints is permitted by a prescription of complementary conditions for each boundary type.\textsuperscript{20,22} For instance, the minimum and maximum constraints of a Dirichlet-type concentration will lead to additional conditions in the following form (it reads: the imposed boundary condition \(C = C_R^F(t)\) is accepted only if the related mass balance flux \(Q_C^R\) (and the related hydraulic head \(h^R\)) is within given min-max bounds, if not, these bounds have to be used as new boundary conditions, where the boundary type has to be changed from a first kind into a flux-type boundary condition of a point sink/source \(Q_C\)

\[
\begin{align*}
Q_C^R < Q_C^{max}(t) & \quad \text{and} \quad Q_C^R > Q_C^{min}(t) \\
\text{and} & \\
\text{else set } Q_C \text{ as an intermediate flux-type condition} & \\
\frac{\partial C}{\partial t} & = 0 \\
\text{according to} & \\
\end{align*}
\]

Fig. 2. Application of transport constraints for saltwater intrusion in flowing groundwater over a salt dome.

boundary point (node) instead of the original first kind boundary condition. Similar expression exist for the other types of boundary conditions. This procedure allows the control of concentration at the boundary, depending on both the balanced flow conditions through the boundary (e.g. \(Q_C^{min} = 0\)) and the location of possible free-surface conditions within the bounds \(h^{min}, h^{max}\). The latter is very important for complex mine flooding processes as studied by Diersch \textit{et al.}\textsuperscript{19}

The computed fluxes \(Q_C^R\) represent lumped (summed-up) mass balance fluxes at nodal points

\[
Q_C^R = - \int_{\Gamma} q_C^R 
\]

Note, the balance quantities are defined positive inward on \(\Gamma\). Actually, the specific balance fluxes \(q_C^R\) are composed by their convective and dispersive parts according to

\[
q_C^R = C_R^F q_{mR}^R - \frac{D_y}{\partial x_i n_j} \frac{\partial C}{\partial x_i}
\]

where \(Q_C^R\) is the mass balance flux at the boundary point to be computed while the \(C_R^F\) condition is imposed, \(Q_C^{max}\), and \(Q_C^{min}\) denote the prescribed time-dependent maximum and minimum bounds, respectively, and \(Q_C\) represents a singular mass sink/source to be set at the

In practice, it has been shown to be inappropriate to include the total (convective plus dispersive) flux into the procedure of controlling the constraint conditions because the direction of dispersive fluxes is ambiguous (e.g. the dispersive spreading also occurs against the
flow direction). Accordingly, the balance-based evaluation of fluxes is exclusively related to the convective mass fluxes

\[
Q^C_R = - \int \rho \mathbf{v} \cdot \mathbf{q}^C_R \approx - \int \left( C^R q^C_R \right)
\]

(12)
giving unambiguously directional balance quantities. Similar expressions can be obtained for the balance of convective heat flux, namely

\[
Q^H_R \approx - \int \left( \rho C_p T q^H_R \right)
\]

(13)

The computation of the convective part of balance fluxes at each controlling (nodal) point is performed via a budget analysis in a postprocessing step. The basic formulation used for computing the above balance quantities is derived in Appendix C.

7 TEMPORAL DISCRETIZATION AND ITERATIVE SOLUTION PROCESS

In general, for more complex flow processes it cannot be predicted which time steps are allowable with respect to the accuracy requirements. Accordingly, a predefined time step marching strategy is often inappropriate and inefficient. Alternatively, stable fully implicit and semi-implicit two-step techniques, known as the GLS (Gresho–Lee–Sani) predictor-corrector time integrator, with automatically controlled stepping of first order by the Forward Euler/Backward Euler (FE/BE) and of second order by the Adams–Bashforth/ Trapezoid Rule (AB/TR), have proven to be powerful and accurate strategies, especially for strong nonlinearities and complex situations. At each time step, the convergence tolerance \( \gamma \) directly governs the time-step size. It provides a cost-effective method in that the step size is increased whenever possible and decreased only when necessary due to the error estimates. The GLS scheme is thoroughly described elsewhere. Here, we will only add modified features which are important in the context of the multiple coupling of equations and constraint computation for the present tasks. Note, a full Newton method is embedded into the AB/TR and FE/BE predictor-corrector methods. The overall adaptive solution process is outlined in Fig. 3.

Denoting the time plane by the subscript \( n \) and the variable time step width by \( \Delta t_n \), the coupled matrix system (8) is solved in the following 22 raw working steps.

**Step 0.** Compute the initial acceleration vectors \( \dot{h}_n, \dot{C}_n \) and \( \dot{T}_n \) for \( n = 0 \) (once per problem)

\[
\begin{align*}
\dot{h}_0 &= F(h_n, C_n, T_n) - S(h_n, C_n, T_n) h_n, \\
\dot{C}_0 &= R(C_n) - D(h_n, C_n, T_n) C_n, \\
\dot{T}_0 &= W(T_n) - L(h_n, C_n, T_n) T_n
\end{align*}
\]

(14)

and guess an initial time step \( \Delta t_0 \).

**Step 1.** Perform explicit predictor solutions by using the AB and FE algorithm, respectively

\[
\begin{align*}
\hat{h}^p_{n+1} &= f_{AB}(\Delta t_n, \Delta t_{n-1}, \dot{h}_n, \dot{h}_{n-1}) , \\
\hat{h}^p_{n+1} &= f_{FE}(\Delta t_n, \dot{h}_n), \\
\hat{C}^p_{n+1} &= f_{AB}(\Delta t_n, \Delta t_{n-1}, \dot{C}_n, \dot{C}_{n-1}) , \\
\hat{C}^p_{n+1} &= f_{FE}(\Delta t_n, \dot{C}_n), \\
\hat{T}^p_{n+1} &= f_{AB}(\Delta t_n, \Delta t_{n-1}, \dot{T}_n, \dot{T}_{n-1}) , \\
\hat{T}^p_{n+1} &= f_{FE}(\Delta t_n, \dot{T}_n)
\end{align*}
\]

(15)

The detailed description of the functions \( f_{AB}() \) and \( f_{FE}() \) can be found in Gresho et al., Bixler, and Diersch.

**Step 2.** Do a corrector solution for the flow equation achieved by the TR and BE scheme, respectively

\[
\begin{align*}
\left( \frac{2}{\Delta t_n} + S(h^p_{n+1}, C^p_{n+1}, T^p_{n+1}) \right) h_{n+1} &= O \left( \frac{h_n + \hat{h}_n}{\Delta t_n} \right), \\
+ F(h^p_{n+1}, C^p_{n+1}, T^p_{n+1}, q^p_n, C_n, T_n) \\
\left( \frac{O}{\Delta t_n} + S(h^p_{n+1}, C^p_{n+1}, T^p_{n+1}) \right) h_{n+1} &= O \left( \frac{h_n}{\Delta t_n} \right), \\
+ F(h^p_{n+1}, C^p_{n+1}, T^p_{n+1}, q^p_n, C_n, T_n)
\end{align*}
\]

(16)

**Step 3.** If constraint conditions are violated, update the matrix system (16) for the new flow boundary values

**Fig. 3.** Adaptive strategy for coupled transient flow, mass and heat transport.
and restart the flow solution with Step 2. If all constraint limits are satisfied continue with Step 4.

Step 4. Solve the Darcy equation
\[
A_{q_{n+1}} = B(h_{n+1}, C_{n+1}, T_{n+1})
\]
(17)

Step 5. Update the new accelerations vectors by 'inverting' the TR and BE, respectively
\[
\hat{h}_{n+1} = \frac{2}{\Delta t_n} (h_{n+1} - h_n) - \tilde{h}_n
\]
\[
\hat{h}_{n+1} = \frac{1}{\Delta t_n} (h_{n+1} - h_n)
\]
(18)

Step 6. Compute the local truncation error of the approximate flow equation for the AB/TR and FE/BE scheme, respectively
\[
d_{n+1}^{\text{flow}} = \frac{h_{n+1} - h_{n+1}}{\left(1 + \frac{\Delta t_{n-1}}{\Delta t_n}\right)}
\]
(19)

Step 7. Predict the potential new time step length from the error estimates of the flow equation
\[
\Delta_{n+1}^{\text{flow}} = \Delta t_n \left(\frac{\gamma}{\|d_{n+1}^{\text{flow}}\|}\right)^{1/\kappa}
\]
(20)

where \(\kappa\) is 3 for the AB/TR and 2 for the FE/BE scheme, \(\gamma\) is a user-specified error tolerance \((\gamma = 10^{-3} - 10^{-5} \text{ is typical})\), and \(\|\cdot\|\) is a norm to be chosen as the weighted RMS
\[
\|d_{n+1}^{\text{flow}}\| = \left[\frac{1}{NP} \sum_{i} \left|h_{i(n+1)} - h_{i(n)}\right|^2\right]^{1/2}
\]
(21)

or, alternatively, as the maximum norm
\[
\|d_{n+1}^{\text{flow}}\| = \frac{\max_{i} \left|h_{i(n+1)} - h_{i(n)}\right|}{h_{\text{max}}}
\]
(22)
in which \(NP\) is the total number of points and \(h_{\text{max}}\) corresponds to the maximum value of the hydraulic head.

Step 8. Tactics for acceptance of the predicted new time step: if the flow solution does not satisfy the prescribed accuracy the time step is reduced by using appropriate formulæ.\(^{17,18}\) and the flow solution is restarted with Step 2. Otherwise, if the accuracy is satisfied, the solution process is continued with Step 9.

Step 9. Perform the corrector solution for the mass transport equation achieved by the TR and BE scheme, respectively
\[
\left(\frac{2P(C_{n+1})}{\Delta t_n} + D(q_{n+1}, C_{n+1}) + J_p(T_{n+1})\right)C_{n+1} =
\]
\[
= P(C_{n+1}) \left(\frac{2}{\Delta t_n} C_n + \hat{C}_n\right)
\]
\[
+ J_p(C_{n+1})C_{n+1} + R(C_{n+1})
\]
(23)

where \(J_p(C_{n+1})\) is the partial (tangential) Jacobian matrix based on the predictor which results from the embodied full Newton approach. Its specific expressions depend on the divergent and convective form of the used transport equation, as given by Diersch.\(^{17}\)

Step 10. If mass constraint conditions are violated, update the matrix system (23) for the new mass boundary values and restart the mass solution with Step 9. Otherwise, continue with Step 11.

Step 11. Update the new acceleration vectors \(\hat{C}_{n+1}\) for the concentration similar to Step 5.

Step 12. Equivalently to Step 6 compute the local truncation error of mass transport \(d_{n+1}^{\text{mass}}\) based on \((C_{n+1} - C_{n+1})\).

Step 13. Estimate the potential new time step from the mass transport computation \(\Delta_{n+1}^{\text{mass}}\), similar to Step 7 by using the error \(d_{n+1}^{\text{mass}}\).

Step 14. Accuracy check of mass transport: reject the current mass transport solution and restart at Step 2 with a reduced time width \(\Delta t_n\) if the required accuracy could not be satisfied. Otherwise, continue with the heat transport solution at Step 15.

Step 15. Perform the corrector solution for the heat transport equation accomplished by the TR and BE scheme, respectively
\[
\left(\frac{2U}{\Delta t_n} + L(q_{n+1}, T_{n+1}) + J_p(T_{n+1})\right)T_{n+1} =
\]
\[
= U \left(\frac{2}{\Delta t_n} T_n + \hat{T}_n\right) + J_p(T_{n+1})T_{n+1} + W(T_{n+1})
\]
(24)
Step 16. If heat constraint conditions are violated update
the matrix system (24) for the new heat
boundary values and restart the heat transport
solution with Step 15. Otherwise, continue with Step
17.

Step 17. Update the new accelerating vectors \( \mathbf{T}_{n+1} \)
for the temperature similar to Step 5.

Step 18. Compute the local truncation transport \( d_{n+1}^{\text{heat}} \)
based on \( T_{n+1} - T_{n+1}^0 \).

Step 19. Estimate the potential new time step from the
heat transport computation \( \Delta t_{n+1}^{\text{heat}} \), similar to Step 7 by
employing the error \( \Delta t_{n+1}^{\text{heat}} \).

Step 20. Accuracy check of heat transport: reject the
current heat transport solution and restart with Step 2
for a reduced time step if the required accuracy could
not be satisfied. Otherwise, continue with Step 21.

Step 21. Determine the new time step length
\[ \Delta t_{n+1} = \min \left( \Delta t_{n+1}^{\text{flow}}, \Delta t_{n+1}^{\text{mass}}, \Delta t_{n+1}^{\text{heat}} \right) \]  
(25)

and restart the time loop with Step 1 as long as the final
time is not reached.

As seen above a constraint violation can lead to
recycling steps around the matrix solution process for
flow, mass and heat transport. The matrix updating
gains efficiency if a total reassembly can be avoided.
Such a procedure of constraint feedback is generally not
restricted in the number of loops. Normally, if constraint
conditions are raised two recycles become sufficient.

To solve the resulting large sparse matrix systems (eqs
(14), (16), (17), (23), (24)) appropriate iterative solvers
for symmetric and unsymmetric equations have to be
applied. For the symmetric positive definite flow
equations the conjugate gradient (CG) method\(^{33}\) is
successful provided a useful preconditioning is applied.
A standard preconditioner, such as the incomplete
factorization (IF) technique\(^{49}\) and, alternatively, a
modified incomplete factorization (MIF) technique,\(^{4}\) based on the Gustafson algorithm, are used. Different
alternatives are available for the CG-like solution of the
unsymmetric transport equations: a restarted
ORTHOMIN\(^{5}\) (orthogonalization-minimization) method,
a restarted GMRES\(^{60}\) (generalized minimal residual)
technique and Lanczos-type methods,\(^{67,71}\) such as CGS\(^{68}\)
(conjugate gradient square), BiCGSTAB\(^{4}\) (bi-conjugate
gradient stable) and BiCGSTAB\(^{34}\) (postconditioned
bi-conjugate gradient stable). For preconditioning, an
incomplete Crout decomposition scheme is currently
applied. Commonly, BiCGSTABFP is the first choice in
our practical simulation of large problems.

8 EXAMPLES OF 2D THERMOHALINE SYSTEMS

8.1 Dimensionless parameters

From a dimensional analysis of the governing balance
equations one can derive the following dimensionless
parameters\(^{54}\) to characterize the convective processes.

Solutal Rayleigh number \( Ra_s \)
\[ Ra_s = \frac{\alpha}{(C_s - C_a)} \frac{\Delta C K_d}{c D_d} \]  
(26)

Thermal Rayleigh number \( Ra_t \)
\[ Ra_t = \frac{\beta \Delta T K_d}{\Lambda} \quad \Lambda = \frac{\epsilon \lambda^4 + (1 - \epsilon) \lambda^4}{\rho' c'} \]  
(27)

Lewis number \( Le \)
\[ Le = \frac{\Lambda}{c D_d} \]  
(28)

Buoyancy ratio (Turner number) \( B \)
\[ B = \frac{\alpha}{(C_s - C_a)} \frac{\Delta C}{\beta \Delta T} \]  
(29)

Accordingly, the relation between the solutal and
thermal Rayleigh number is given by
\[ Ra_t = B Le Ra_s \]  
(30)

From perturbation analysis along the thermohaline
Horton–Rogers–Lapwood (HRL) problem\(^{54}\) the critical
Rayleigh number \( Ra_c \) is composed of solutual and
thermal influences. It can be shown for the HRL
problem that the boundary between stable and unstable
convection possesses a straight line, namely
\[ Ra_c = Ra_s + Ra_t \]  
(31)

The critical Rayleigh number \( Ra_c \) depends on boundary
conditions, geometry and anisotropy. A first critical
number \( Ra_{c1} \) describes the onset of convection in the
form of stable stationary rolls, which is normally given by
\( 4 \pi^2 \). A further increase of the Rayleigh number leads
to a second critical stage characterized by \( Ra_{c2} \).
For this regime no more stationary conditions exist and fluctuating
(oscillatory) transient convective patterns appear.\(^{55,56,57,58,65}\)
\( Ra_{c2} \) is only known from numerical studies,\(^{55,56,57,58,65}\)
where a value of about 390 is reported. For 3D cases it
has been found that the final convective structures are
dependent on the initial conditions. Stable convection
could be recognized only if raised as 2D roll cells.
Otherwise, the 3D state has been found to be unstable
from the beginning,\(^{76}\) soon above criticality.
8.2 The 2D thermohaline Elder problem

8.2.1 Definition of the problem

The 2D saline Elder problem is expanded to a thermohaline convection process if the salinity field is augmented by a thermal distribution as defined in Fig. 4. The geometry is given by the aspect ratio $A = L/d$ of 4 and a so-called intrusion ratio $I = e/L = 0.5$. While the homogeneous aquifer is permanently heated from below, the salinity gradient acts from above. The normalized concentration on the top of aquifer is greater than zero in the central section. On the bottom of the aquifer the salinity is held at zero. On the other hand, the top and bottom boundaries are held at constant temperatures as indicated in Fig. 4. Otherwise, all remaining boundary portions are considered impervious for solute and adiabatic (insulated) for heat. All boundaries are impervious for fluid flow. As a reference for the hydraulic head a single boundary value of $h = 0$ has to be set at one mode (normally in the centre of the mesh). The used model parameters are summarized in Table 1.

As stated above, such a formulation of the thermohaline Elder problem can be considered as a mixed DDC regime where a finger regime dominates at the beginning (cool salinity sinks down) and later a more diffusive regime occurs (downsunk salinity is heated from below). The finite element meshes as shown in Fig. 5, which have proven to be capable of attaining convergent solutions for the Elder problem, are also used for the following investigations.

8.2.2 Results and discussion

The basis for comparison is the thermohaline simulation for the pure saline free convection, i.e. $Ra = 0$ and $B = \infty$, as presented in the first part of this paper. It meets the best numerical approximation available for this case: divergent formulation of the mass transport equation, extended Boussinesq approximation, Galerkin-FEM, and a predictor-corrector AB/TR time integrator. As the convergence tolerance $\gamma$ a value of $10^{-3}$ is used both for head $h$, salinity $C$ and temperature $T$ based on a RMS error norm (cf. eqn (21)).

To study the growing influence of thermohaline convection more in detail we consider the computational results using mesh A for decreasing buoyancy ratios $B = \infty, 5, 4, 3, 2$ as exhibited in a series in Fig. 6. While the results for $B = 5$ (Fig. 6(b)) are still rather similar

8.3 The 2D thermohaline salt dome problem

8.3.1 Definition of the problem

The considered test case is an idealization of the flow over a salt dome,\textsuperscript{32,43,44,55} where the geometry is greatly simplified. The geometry and boundary conditions used are shown in Fig. 9. The cross-section of the model extends horizontally 900 m and vertically 300 m having an aspect ratio $A$ of 3. The aquifer is considered to be homogeneous and isotropic. The hydraulic head varies linearly on the top of the aquifer. All remaining boundaries are impervious to flow. The salinity on the top is taken equal to zero (freshwater) over the entire boundary. Additionally, a minimum mass flux constraint condition of $Q_{Cm} = 0$ is imposed. This ensures that the freshwater condition is only valid if the flow enters the domain. The middle section of the aquifer base represents the cap of the salt dome having a relative salt concentration equal to unity. The thermohaline extension of the salt dome problem concerns a superimposition of a thermal gradient acting upward and it tends to destabilize the brine pool due to the arising buoyant forces. Accordingly, the bottom of the aquifer is assigned by a constant normalized temperature of $T = 1$, while the top boundary is imposed by a normalized temperature of zero ($T = 0$). Again, the upper boundary is additionally constrained by a minimum heat flux of zero $Q_{T} = 0$ which permits a control of the boundary conditions for inflowing and outflowing situations. The side walls of the domain are regarded as impervious for solute mass and advective (insulated) for heat. The model parameters are summarized in Table 2. According to the DDC classification as stated above, the formulation of the thermohaline salt dome problem is one of a diffusive regime where the buoyancy force is caused by heat, which has a larger diffusivity than salt.

The finite element mesh as shown in Fig. 10 is used for the simulations of the thermohaline salt dome problem. The predictor-corrector AB/ATR time integrator with a RMS-based convergence tolerance $\gamma$ of $10^{-3}$ is applied.

8.3.2 Results and discussion

Simulated results of the salt dome problem at a time of 100 years for different buoyancy ratios $B$ are shown in Fig. 11. It reveals that the temperature effect on the saltwater distribution remains negligible or small if compared with the single-diffusive results\textsuperscript{43} at higher buoyancy ratios $B$. As seen for $B = 2$, however, if the buoyancy ratio becomes smaller, vigorous temperature influences on the brine pattern result in form of a ‘wavy’ salinity field caused by the thermal buoyancy.

To illustrate how such a thermal effect on the brine flow is evolved a series of salinity and temperature patterns are outlined in Fig. 12 for the case of $B = 2$. The ‘wavy’ salinity characteristics are triggered in front of the salt wedge by thermally driven eddies. As
Fig. 6. Influence of thermohaline convection: computed salinity distributions of 0.2 and 0.6 normalized isochlor at 1, 2, 4, 10, 15 and 20 years (from left to right) for different buoyancy ratios (a) $B = \infty$; (b) $B = 5$; (c) $B = 4$; (d) $B = 3$; and (e) $B = 2$ by using mesh A.
expected, it leads to an increased saltwater effluent on top of the aquifer. Note, that a buoyancy ratio of 2 implies an already large temperature difference for a high-concentration brine and, accordingly, corresponds to an extreme situation. It should be mentioned that for the real site behind the present salt dome problem such high temperatures corresponding to $B = 2$ may be unlikely to occur in practice. However, the variants can be valuable as test cases to study the effects of high temperatures, which may, for instance, arise in the vicinity of a disposal facility for heat-emitting waste.

9 EXAMPLES OF 3D CELLULAR CONVECTION

9.1 The 3D Elder problem for single-diffusive (solutal) and double-diffusive (thermohaline) convection

9.1.1 Definition of the problem

Originally, the Elder problem\textsuperscript{23} refers to a 2D cross-sectional convection process in a fluid-saturated porous layer. As a result, only 2D roll cells can appear. Now, interest is focused on adequate 3D situations. For this purpose the Elder problem is expanded for both single-diffusive and double-diffusive applications in a porous box consisting of a square base \((L \times L)\) and height \(d\). This box has the same cross-sections along the Cartesian

| Table 2. Simulation parameters for the 2D thermohaline salt dome problem |

Fig. 10. Finite element mesh used for 2D thermohaline salt dome problem consisting of 1920 elements and 2013 nodes.

axes as defined in Fig. 4 for the 2D sketch. Boundary conditions and measures are identical to the 2D case shown in Fig. 4. Now, salinity is held constant, in an areal extent, on the top and bottom of the porous box. The used parameters correspond to those given in Table 1.

The box is discretized by hexahedral trilinear finite elements as displayed in Fig. 13. To reduce the computation effort only a quarter of the discretized domain is actually simulated. It is based on the assumption that symmetric planes occur for the studied range of Rayleigh numbers. Both AB/TR and FE/BE time marching with a RMS-based convergence tolerance \( \gamma \) of \( 10^{-3} \) have been tested. For the long-term simulations and the chosen spatial resolution the second-order AB/TR scheme with a full Newton method becomes sensitive and produces oscillations at later simulation times. On the other hand, the first-order FE/BE scheme with full Newton method has proven to be more stable and robust and, therefore, it is preferred for the present 3D simulations. Generally, Galerkin-FEM (i.e. no upwinding) is used. To simulate the convection process over a period of 100 years the FE/BE scheme takes 641 time steps for the single-diffusive problem and 965 time steps for the double-diffusive (thermohaline) problem (excluding restarted steps).

9.2.2 Results and discussion

The 3D free convection process is similar to the 2D counterpart, with some interesting new features. To give more insight into the physics of the 3D convection process, Fig. 14 shows the evolution of salinity from different views. The 3D cut-away images (left column of Fig. 14) display the progressing fingering characteristics in the 3D space. Similar to the 2D case we also find an upwelling salinity pattern in the centre of the box at the given time stages. The 3D influence also becomes apparent in the two horizontal views at an upper elevation of \( 0.9 \, d \) (135 m) and the middle horizon of \( 0.5 \, d \) (75 m) as shown in Fig. 14. At the beginning, the quadratic geometry of the intrusion area on top is visible in the convection pattern. Fingers appear around the border of the intrusion area and 'blobs' grow down at the four corners. The quadratic pattern evolves into more complicated multicellular formations via a number of characteristic stages. More 'blobs' appear up to the time when the salinity reaches the bottom. Then, the structures begin to fuse and the pattern is completely reformed. After this phase a convection pattern remains which has a characteristic diagonal 'star' form. This 'star' is a result of the geometry of the square intrusion area. It becomes clear that the final formations have a strong dependency on the geometric relations.

An illustration of the pattern evolution in 3D space is given in Fig. 15 where isosurfaces of the 50% salinity are shown at characteristic time stages. Up to a time of about 4 years the salinity primarily sinks down and forms a dissected finger formation. At later

Fig. 11. Evolution of the thermohaline convection system: computed salinity and temperature distributions at 100 years for different buoyancy ratios (a) \( B = 5 \); (b) \( B = 3 \); and (c) \( B = 2 \).
Fig. 12. Evolution of the thermohaline convection system: computed salinity and temperature distributions at several times for a buoyancy ratio of $B = 2$.

time the upper part contracts and forms the typical diagonal 'star', while larger 'blobs' are getting fused below.

The 3D thermohaline Elder problem has been simulated for a buoyancy ratio of $B = 5$, where the solutal Rayleigh number $Ra_s$ is again 400. The 3D distributions of the computed salinities and temperatures for up to 20 years are displayed in Fig. 16. In contrast to the single-diffusive formation (cf. Fig. 14) the salinity pattern appears more diffusive at later times when the temperature field affects the convection system. Then, the thermally buoyant forces accelerate the contraction process of the sinking salinity plume in the centre. In the final stage, while the single-diffusive convection still provides an upwelling flow in the centre, the thermohaline convection process reveals a single downwelling characteristics for the salinity (see Figs 15 and 17). As seen, the most heated water is buoyantly affected outside and around the denser salinity core, where the isotherms come to the upper locations. These mutual influences between salinity and temperature are more apparent in Figs 17 and 18 for the computed isosurfaces of salinity and temperature, respectively.

Fig. 13. Total finite element mesh for the 3D Elder problem: only a quarter of the mesh is actually used in the computation. This quarter consists of 48,000 hexahedral elements and 51,701 nodes.

Fig. 14. Computed salinity patterns of the 3D Elder problem at times of (a) 1; (b) 2; (c) 4; (d) 10 and (e) 20 years.

Fig. 15. Computed 3D isosurfaces of 50% salinity for the 3D Elder problem (viewing into the box from bottom to top) at times of (a) 1; (b) 2; (c) 4; (d) 10; (e) 15 and (f) 20 years.
234623 (101 × 101 × 23) nodes. Again, for the temporal discretization the FE/BE predictor-corrector scheme with the full Newton method and a RMS-based convergence tolerance γ of 10^{-3} is applied to the simulation.

9.2.2 Results and discussion
The striking features of 3D Bénard convection development are shown in Fig. 19. The initial motion is characterized by a rectangular string of end-cells where, at the four corner points, the most intensive growths of 'blobs' can be observed. It is followed by a growth of cells starting from the ends of the intrusion area on top. At these times a remarkable feature of the 3D convection process is the annular roll pattern formation. At smaller times the cell structures are rather complex (Fig. 19(b)) showing the birth of subcellular eddies both across and along the annular structure. Due to the smaller Rayleigh number the nonroll-like perturbations are smoothed at larger times and the convection process results in a highly regular pattern of ring structures.

10 Closure
The finite-element method is applied to simulate variable density flow processes in 2D and 3D groundwater systems. The described solution strategies as implemented in the simulator FEFLOW are more general and are primarily developed to tackle complex practical applications where solutal and/or thermal density effects play an important role. However, before more complex field situations can be studied the chosen methods and codings have to be extensively tested over a wider spectrum of this important class of non-linear problems. In this context the aim of the present paper is mainly proving and benchmarking of the simulations along examples where comparable results are available, or if not, the obtained results are to be supposed as a comparison basis for further studies. We have chosen the Elder and salt dome problem (HYDROCOIN case 5 level 1) as well suited and representative examples. They allow us both to participate in the process of resolving partly contradictory results given in the literature and to expand (or generalize) the 2D solutions to three dimensions and additional coupling phenomena from a well-documented and accepted source. The extensions concern thermohaline and multicellular convection processes in 2D and 3D. Unfortunately, to date both numerical and experimental results of 3D and thermohaline convection are rare and we are mostly dependent on an incremental procedure in comparing and interpreting the results among one another. In this context we found similarities and also interesting new features regarding the pattern formations of the buoyancy-driven convection processes.
Fig. 17. Computed 3D isosurfaces of 50% salinity for the 3D thermohaline Euler problem (viewing from bottom to top) at \( B = 5 \) and times of (a) 1; (b) 2; (c) 4; (d) 10; (e) 15 and (f) 20 years.

Fig. 18. Computed 3D isosurfaces of 50% temperature for the 3D thermohaline Euler problem (viewing from top to bottom) at \( B = 5 \) and times of (a) 1; (b) 2; (c) 4; (d) 10; (e) 15 and (f) 20 years.
The interaction between solutal and thermal convection is studied by varying the buoyancy ratio $B$, which expresses the relationship between buoyancy forces due to solutal and thermal convection. Differences between (pure) saline convection and thermohaline convection become apparent for buoyancy ratios $B \leq 5$. We found asymmetric convection patterns for buoyancy ratios near to unity. In this situation, the hydrodynamic system becomes strongly unstable because the solutal and thermal buoyancy effects are nearly equilibrated. As a result, very small vertical velocities trigger the convection process. Grid effects indicate the physical instability. The numerical solution of thermohaline convection systems with buoyancy ratios near to unity requires extremely fine spatial discretizations.

Three-dimensional convection needs sufficiently high spatial and temporal resolutions if damping measures, such as upwinding, are to be avoided. At moderate Rayleigh numbers (400 for the 3D Elder problem and 200 for the 3D Bénard convection; we used more than 50,000 nodes for a quarter of the domain and about 230,000 nodes for the total discretization of a 3D porous layer subjected to a free convection process. In comparison with 2D, where it has been found that about 10,000 nodes are required to accomplish satisfactorily accurate results for the Elder problem, the chosen 3D resolution seems to be a minimum for this class of problems. Time marching is based on a predictor-corrector strategy with an automatic time step control embedded in a one-step full Newton method. For the present examples more than 600 intrinsic time steps are required for simulating a 3D convection process with a duration of about 20 years for a convergence tolerance $\gamma$ of $10^{-3}$.

It becomes clear that a long-term analysis of 3D free or thermohaline convection takes a large numerical effort and is normally a time-consuming task. While a 2D simulation is still on the order of hours of CPU time, a 3D problem can take days of runtime on a workstation. However, by using a high-speed workstation available today the 3D Elder problems and the Bénard convection could be solved in one day and two days of runtime, respectively. It should be taken into consideration that the FEFLOW code is general and not streamlined, for instance, for special cases of free convection in rectangular domains with homogeneous parameters. That means the impact and the found efforts are representative for general problems having an arbitrary geometry and permitting such parametric and boundary conditions which are required in actual site-specific applications.

APPENDIX A

Weak form of the continuity eqn (1)

\[ \int_{\Omega} s \frac{\partial \phi}{\partial t} \, d\Omega - \int_{\Omega} \frac{\partial \omega}{\partial x_j} q_{\phi}^{\omega} = - \int_{\Gamma} w q_{\phi}^{\alpha} n_l + \int_{\Omega} w (Q_p + Q_{EB}) \]  

\( (A1) \)

Introducing the Darcy eqn (2) into eqn (1) and taking into account that the buoyancy term leads to

\[ \frac{\rho^\alpha - \rho^\alpha_r}{\rho^\alpha} = \frac{\alpha}{(C_s - C_o)(C - C_o)} - \beta(T - T_0) \]  

\( (A2) \)

by using the fluid density equation of state (5), following final weighted residual formulation of the continuity equation results

\[ \int_{\Omega} s \frac{\partial \phi}{\partial t} \, d\Omega + \int_{\Omega} \frac{\partial w}{\partial x_j} K_{\phi \phi} \frac{\partial \phi}{\partial x_j} \]

\[ = - \int_{\Omega} \frac{\partial w}{\partial x_j} K_{\phi \phi} \left[ \frac{\alpha}{(C_s - C_o)} (C - C_o) \right. \]

\[ - \left. \beta(T - T_0) \right] q_{\phi}^{\alpha} \, d\Omega \]

\[ - \int_{\Omega} w q_{\phi}^{\alpha} \frac{\partial C}{\partial x_j} - \beta \frac{\partial T}{\partial x_j} \, d\Omega \]

\[ - \int_{\Gamma} w q_{\phi}^{\alpha} n_l + \int_{\Omega} w Q_p \]  

\( (A3) \)

where the extended Boussinesq approximation term (7) is incorporated. Eqn (A3) represents the standard weak
form of the substitution formulation to solve the hydraulic head \( h \).

**Weak form of the Darcy eqn (2)**

Formally, a weak form of the Darcy equation can easily be derived as

\[
\int_{\Omega} w q_i^f = - \int_{\Omega} w K_{ij} \frac{\partial h}{\partial x_j} - \int_{\Omega} w K_{ij} \left( \frac{\alpha}{(C - C_o)} (C - C_o) \right) - \beta (T - T_o) e_j
\]  

(A4)

to solve the vector of Darcy fluxes \( q_i^f \) at given \( h \), \( C \) and \( T \).

**Weak form of the mass transport eqns (3)**

The weak formulations for the divergent and convective forms of the contaminant mass conservation equations differ from the fact that for the former, the divergence theorem is applied both to the convective and the dispersive terms

\[
\int_{\Omega} w \frac{\partial}{\partial x_i} (q^f C - D_{ij} \frac{\partial C}{\partial x_j}) = \int_{\Gamma} w \left( C q_i^f - D_{ij} \frac{\partial C}{\partial x_j} \right) n_i + \int_{\Omega} w \frac{\partial C}{\partial t} \tag{A5}
\]

while the conventional convective form applies the divergence theorem only to the dispersive (second order) term

\[
\int_{\Omega} w \frac{\partial}{\partial x_i} \left( D_{ij} \frac{\partial C}{\partial x_j} \right) = \int_{\Omega} \frac{\partial w}{\partial x_i} D_{ij} \frac{\partial C}{\partial x_j} + \int_{\Gamma} w D_{ij} \frac{\partial C}{\partial x_j} n_i \tag{A6}
\]

Finally, it yields the following weak formulations

\[
\int_{\Omega} w R_{D} \frac{\partial C}{\partial t} - \int_{\Omega} \frac{\partial w}{\partial x_i} q_i^f C + \int_{\Omega} \frac{\partial w}{\partial x_i} D_{ij} \frac{\partial C}{\partial x_j} + \int_{\Omega} w R \theta C
\]

\[= \int_{\Omega} w Q_C - \int_{\Gamma} w q_i^{\text{total}} \tag{A7}
\]

for the divergent form and

\[
\int_{\Omega} w R_{D} \frac{\partial C}{\partial t} + \int_{\Omega} w q_i^f \frac{\partial C}{\partial x_i} + \int_{\Omega} \frac{\partial w}{\partial x_i} D_{ij} \frac{\partial C}{\partial x_j} + \int_{\Omega} w (R \theta + Q_p) C
\]

\[= \int_{\Omega} w Q_C - \int_{\Gamma} w q_i^{\text{disp}} \tag{A8}
\]

for the convective form, respectively, to solve the concentration \( C \).

**Weak form of the heat transport eqn (4)**

Similar to the above, the weak formulation of the convective form of the heat transport equation is given by

\[
\int_{\Omega} \left[w \left[c \rho^\prime \epsilon \epsilon + (1 - \epsilon) \rho \epsilon^\prime \epsilon^\prime \right] \frac{\partial T}{\partial t} + \int_{\Omega} w \rho^\prime \epsilon \epsilon^\prime q_i^f \frac{\partial T}{\partial x_i} + \int_{\Omega} \frac{\partial w}{\partial x_i} \lambda \frac{\partial T}{\partial x_i} \right] n_i = \int_{\Omega} w Q_T - \int_{\Gamma} w q_i^{\text{cond}} \tag{A9}
\]

for solving the temperature \( T \).

**Finite element formulations**

Employing the Galerkin version of the FEM (GFEM), \( w_m = N_m \), for the above weak formulations and replacing the \( h \), \( q_i^f \), \( C \) and \( T \) variables by their trial approximations

\[
\begin{align*}
& h(x_i, t) \equiv \hat{h}(x_i, t) = \sum_{m} N_m(x_i) h_m(t) \\
& q_i^f(x_i, t) \equiv \hat{q}_i^f(x_i, t) = \sum_{m} N_m(x_i) q_i^{fm}(t) \\
& C(x_i, t) \equiv \hat{C}(x_i, t) = \sum_{m} N_m(x_i) C_m(t) \\
& T(x_i, t) \equiv \hat{T}(x_i, t) = \sum_{m} N_m(x_i) T_m(t)
\end{align*}
\]  

(A10)

the matrix coefficients of eqn (8) are as follows

\[
\begin{align*}
O_{mn} &= \int_{\Omega} S_{n} N_{m} N_{n} \quad A_{mn} = \int_{\Omega} N_{m} N_{n} \\
P_{mn} &= \int_{\Omega} R_{D} N_{m} N_{n} \quad U_{mn} = \int_{\Omega} \left[R \rho^\prime \epsilon \epsilon^\prime + (1 - \epsilon) \rho \epsilon^\prime \epsilon^\prime \right] N_{m} N_{n} \\
S_{mn} &= \int_{\Omega} K_{ij} \frac{\partial N_{m}}{\partial x_{i}} \frac{\partial N_{n}}{\partial x_{j}} \\
D_{mn} &= \int_{\Omega} \left[ - \frac{\partial N_{m}}{\partial x_{i}} q_{i}^{fm} N_{n} + D_{ij} \frac{\partial N_{m}}{\partial x_{i}} \frac{\partial N_{n}}{\partial x_{j}} \right] + R \theta N_{m} N_{n} \tag{A11}
\end{align*}
\]

\[
\begin{align*}
D_{mn} &= \int_{\Omega} \left[ N_{m} q_{i}^{f} \frac{\partial N_{n}}{\partial x_{i}} + D_{ij} \frac{\partial N_{m}}{\partial x_{i}} \frac{\partial N_{n}}{\partial x_{j}} \right] + (R \theta + Q)p N_{m} N_{n} \tag{A12}
\end{align*}
\]

\[
L_{mn} = \int_{\Omega} \left[N_{m} \rho^\prime \epsilon \epsilon^\prime q_{i}^{f} \frac{\partial N_{n}}{\partial x_{i}} + \lambda_{ij} \frac{\partial N_{m}}{\partial x_{i}} \frac{\partial N_{n}}{\partial x_{j}} \right] \tag{A13}
\]
\[ F_m = - \int_{\Omega} \left[ \frac{\partial N_m}{\partial x_i} K_{ij} \mu \left( \frac{\alpha}{(C_s - C_o)} (\dot{C} - C_o) \right) \right] \delta_j - \int_{\Omega} N_m q_{\text{fc}} \left( \frac{\alpha}{(C_s - C_o)} \frac{\partial C}{\partial x_i} \right) \delta_j - \beta \left( \dot{T} - T_o \right) \delta_j - \beta \frac{\partial T}{\partial t} \delta_j \int_{\Gamma} N_m q_{\text{nt}} + \int_{\Gamma} N_m Q_T \]

\[ B_m = - \int_{\Omega} N_m K_{ij} \frac{\partial h}{\partial x_j} \delta_j - \int_{\Omega} N_m K_{ij} \mu \left( \frac{\alpha}{(C_s - C_o)} (\dot{C} - C_o) \right) \delta_j - \beta \left( \dot{T} - T_o \right) \delta_j \int_{\Gamma} N_m Q_J + \int_{\Gamma} N_m Q_T \]  

\[ R_m = \int_{\Omega} N_m Q_J - \int_{\Gamma} N_m q_{\text{total}} \text{ divergent form} \]

\[ R_m = \int_{\Omega} N_m Q_J - \int_{\Gamma} N_m q_{\text{disp}} \text{ convective form} \]

\[ W_m = \int_{\Omega} N_m Q_T - \int_{\Gamma} N_m q_{\text{nt}} \text{ cond} \]

Results in a system of linear equations to solve the smoothed velocities \( q_{\text{fc}} \), namely

\[ \sum_n M_{mn} q_{\text{fc}} = Z_{im} \]  

(B5)

where \( M_{mn} \) represents the mass matrix and \( Z_{im} \) is the RHS involving the unsmoothed relations. They are formed in the finite element assembling procedure as

\[ M_{mn} = \int_{\Omega} N_m N_n \]

(B6)

and, by inserting the Darcy velocity components, as

\[ Z_{im} = \int_{\Omega} N_m q_{\text{fc}} \]

\[ = - \int_{\Omega} N_m \left[ K_{ij} \mu \left( \frac{\partial h}{\partial x_j} + \left( \frac{\alpha}{(C_s - C_o)} \right) (\dot{C} - C_o) \right) - \beta \frac{\partial T}{\partial t} \right] \delta_j \]

(B7)

Note, the least square approximations of global smoothing (B7) is equivalent to the Galerkin weighting procedure (A16) in Appendix A.

A cost-effective alternative appears if the mass matrix \( M_{mn} \) is lumped by an row-sum or diagonal scaling

\[ M_{mn} = \begin{cases} \int_{\Omega} N_m \left( \sum_N N_n \right) & m = n \\ 0 & m \neq n \end{cases} \]

(B8)

without need to solve the linear equation system (B5).

**APPENDIX B**

**Global smoothing of discontinuous velocity fields**

A global approximation of the smoothed Darcy velocities can be written as

\[ q_{\text{fc}}(x_i) = \sum_m N_m(x_i) q_{\text{fc}}^m \]

(B1)

Assume that we have an unsmoothed (discontinuous) velocity field \( q_{\text{fc}}(x_i) \), then the smooth function which provides a best fit in the least squares sense over the domain \( \Omega \) can be obtained from a minimization of the functional

\[ J = \int_{\Omega} \left( q_{\text{fc}} - q_{\text{fc}}^m \right)^2 \rightarrow \text{Min} \]

(B2)

The minimization procedure

\[ \frac{\partial J}{\partial q_{\text{fc}}^m} = \int_{\Omega} 2 \left( q_{\text{fc}} - q_{\text{fc}}^m \right) \frac{\partial q_{\text{fc}}^m}{\partial q_{\text{fc}}^m} = 0 \quad \text{for} \quad m = 1, 2, \ldots \]

(B3)

or

\[ \int_{\Omega} N_m \left( q_{\text{fc}} - q_{\text{fc}}^m \right) = 0 \]

(B4)

The discontinuous velocity in each element \( e \)

\[ q_{\text{fc}}^e = - K_{ij} \mu \left( \frac{\partial h}{\partial x_j} + \left( \frac{\alpha}{(C_s - C_o)} \right) (\dot{C} - C_o) \right) - \beta \left( \dot{T} - T_o \right) \delta_j \]  

(B9)

is computed at the Gauss points \( p (2 \times 2 \times 2) \) for linear and \( 3 \times 3 \times 3 \) for quadratic elements) with given approximations of the hydraulic head \( h^e \), concentration \( C^e \), and temperature \( T^e \) for element \( e \) from previous solutions.

**Step 1.** The values at the Gauss points are assigned to
the nearest corner node $p \rightarrow m$. Each nodal contribution is summed up and, at the end, the nodal values are averaged by their number of nodal contributions $n_p$ from the patch sharing the node $m$.

$$ q_{im}^e = \left( \sum_{e} q_{im}^{e*} \right) / n_p \quad (B10) $$

**APPENDIX C**

**Auxiliary problem formulation used for budget flux computation of the convective part**

The budget analysis aims at the computation of the normal convective mass (or heat) fluxes $Q^R_C = \sum \int_{\Gamma} (C^R q^R_m \hat{r})$. Multiplying each term of the continuity eqn (1) by concentration $C$ we get the weak form

$$ \int \omega w C \frac{\partial q^f_i}{\partial x_i} = \int \omega w C (Q^p + Q_{EB}) - \int \omega w C S^o \frac{\partial h}{\partial t} \quad (C1) $$

It is further

$$ \frac{\partial (w C q^f_i)}{\partial x_i} = C q^f_i \frac{\partial w}{\partial x_i} + w C \frac{\partial q^f_i}{\partial x_i} + w q^f_i \frac{\partial C}{\partial x_i} \quad (C2) $$

Employing the divergence theorem on the LHS of identity (C2) we obtain from (C1) and (C2)

$$ \int \Gamma w C q^f_i n_i = \int \omega C \frac{\partial w}{\partial x_i} q^f_i + \int \omega w C \frac{\partial q^f_i}{\partial x_i} + \int \omega w C (Q^p + Q_{EB}) - \int \omega w C S^o \frac{\partial h}{\partial t} \quad (C3) $$

It has been found to evaluate the individual terms of eqn (C3) in different ways. While the velocity $q^f_i$ in the first term of the RHS is expressed by the Darcy law, the second RHS term uses explicitly the velocity from the computation. The LHS surface integral describes already the desired convective mass flux along the boundary portion $\Gamma$, where $q^R_m = q^R_m |_{\Gamma}$ is the normal fluid flux and $q^R_m = C q^R_m |_{\Gamma} = C q^R_m |_{\Gamma}$ is the normal convective mass flux through the boundary.

Finally, following finite element formulation results in computing the normal convective mass flux from given solutions (A10) of hydraulic head $h$, Darcy flux $q^f_i$, concentration $C$, and temperature $\hat{T}$

$$ \int \Gamma N^R_m q^R_m = - \int \omega K_{\text{id}} \frac{\partial N^R_m}{\partial x_i} \frac{\partial N^R_n}{\partial x_j} (N_k C_k) h_n $$

$$ - \int \omega K_{\text{id}} \frac{\partial N^R_m}{\partial x_i} (N_k C_k) \left[ \frac{\delta}{(C_k - C_0)} (\hat{C} - C_0) \right] $$

$$ - \hat{\beta} (\hat{T} - T_0) \delta_j $$

$$ + \int \omega N_m \left( \frac{\partial N^R_n}{\partial x_i} C_n \right) (N_k q^R_k) $$

$$ + \int \omega N_m (N_k C_n) (Q^p + Q_{EB}) $$

$$ - \int \omega N_m (N_k C_n) S^o \left( N_k \frac{\partial h}{\partial t} \right) \quad (C4) $$

All contributions of mass flux are summed up at node $m$ to obtain the lumped nodal balance mass flux $Q^R_C$ in the form

$$ Q^R_C = - \int \Gamma q^R_C = - \sum_{e} \int_{\Gamma_e} N_m q^R_m \quad (C5) $$

which is defined positive inward and will be used for the boundary constraint control (see Section 6). Similar expressions to (C4) and (C5) can be derived for heat balance fluxes if $\rho \hat{C}^{\hat{T}}$ is used as a multiplier.
